BUDGET ALLOCATION

Single Phase

The problem can be formulated as:

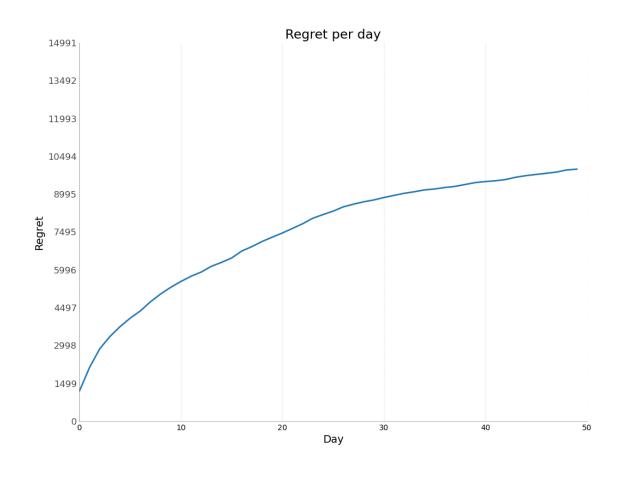

$$\begin{cases} \max_{y_j} \sum_{j}^{N} n_j(y_j) \\ \sum_{j}^{N} y_j < Y \end{cases}$$

Setup

- 11 possible budgets, from 5000\$ to 10000\$ sampled every 500\$
- Budget cap of 27000\$
- Repeat execution for 50 days

Setup

- 11 possible budgets, from 5000\$ to 10000\$ sampled every 500\$
- Budget cap of 27000\$
- Repeat execution for 50 days

- Rapid increase in first few days
- Stabilization after few days
- Solution found is coherent with ideal solution

BUDGET ALLOCATION

3 Phases

The problem can be formulated as:

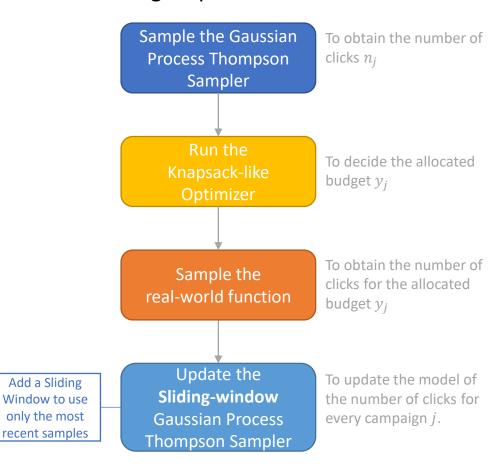

$$\begin{cases} \max_{y_j} \sum_{j=1}^{N} n_j(\mathbf{t}, y_j) \\ \sum_{j=1}^{N} y_j < Y \end{cases}$$

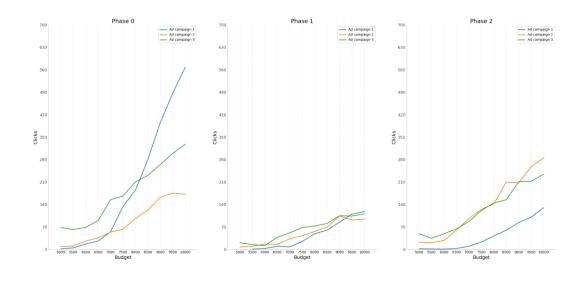

Differently from the one phase model, the optimal solution depends on the time *t*.

The window size is calculated as:

$$size = c * \sqrt{T}$$

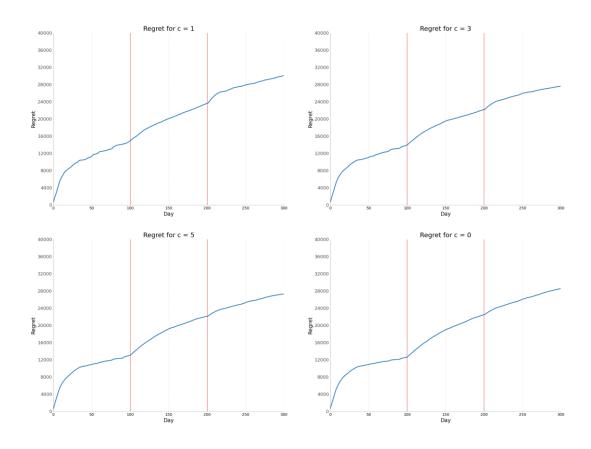

Where *c* is a coefficient and *T* is the time horizon.

Setup

- 11 possible budgets, from 5000\$ to 10000\$ sampled every 500\$
- Budget cap of 27000\$
- The phase changes every 100 days
- Executed for 300 days
- Repeated for different values of c

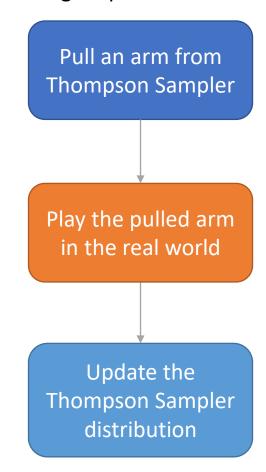

Setup

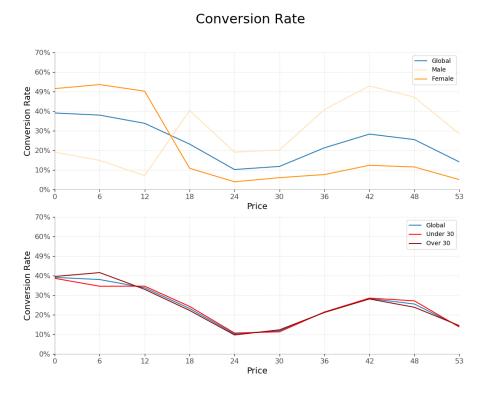

- 11 possible budgets, from 5000\$ to 10000\$ sampled every 500\$
- Budget cap of 27000\$
- The phase changes every 100 days
- Executed for 300 days
- Repeated for different values of *c*

- No window (c = 0) best in first phase
- \sim 34 days window best in the end
- No windows is better in static context, windowed better in dynamic ones
- Performances vary with window sizing

PRICING

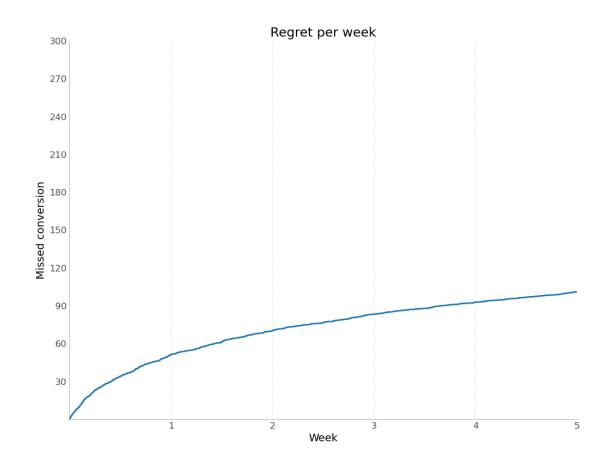

Our objective is to find which price will result in the best conversion rate possible.

Setup

- 10 possible prices
- Changing price every 10 minutes
- Simulating for 5 weeks

Setup

- 10 possible prices
- Changing price every 10 minutes
- Simulating for 5 weeks

- Rapid increase in first days
- Stabilizes later on
- Small increases due to exploration

PRICING

Context Learning

Our objective is to find which price will result in the best conversion rate possible.

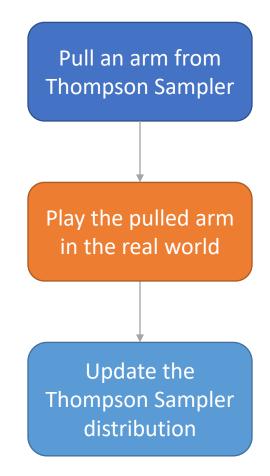

We also want to find a partitioning of users in context. We use a decision tree, splitting when:

$$\mu$$

Where:

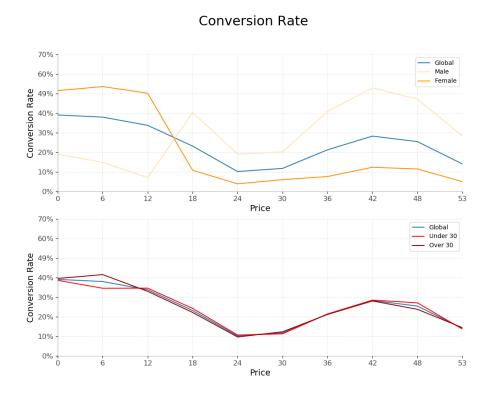

- μ is the information before the split
- p is the probability of attribute a being equal to 1
- $\mu_{a_1}^*$ is the information obtained by playing arm a^* when attribute a=1
- $\mu_{a_0}^*$ is the information obtained by playing arm a^* when attribute a=0

For every day t, we run the following loop:

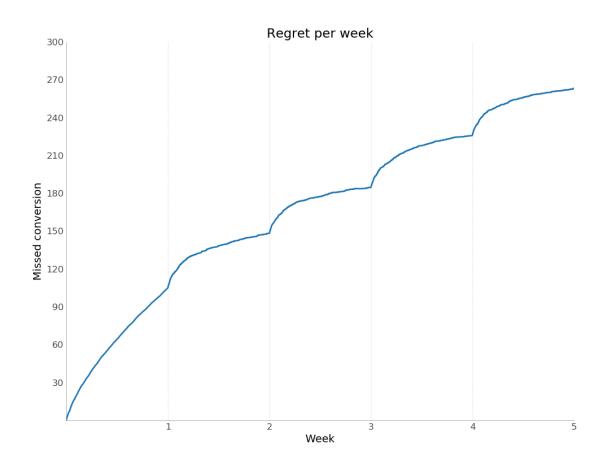

At the end of every week, we generate a new context by:

Run the clustering algorithm

Setup

- 10 possible prices
- Changing price every 10 minutes
- Simulating for 5 weeks
- New context generation at the end of every week
- Initial context based on age and not sex (worst case)

Setup

- 10 possible prices
- Changing price every 10 minutes
- Simulating for 5 weeks
- New context generation at the end of every week
- Initial context based on age and not sex (worst case)

- Worst performance in first week
- Performance get better as soon as new context are generated
- New contexts are based on sex (but sometimes also on age)

SIMULTANUES OPTIMIZATION

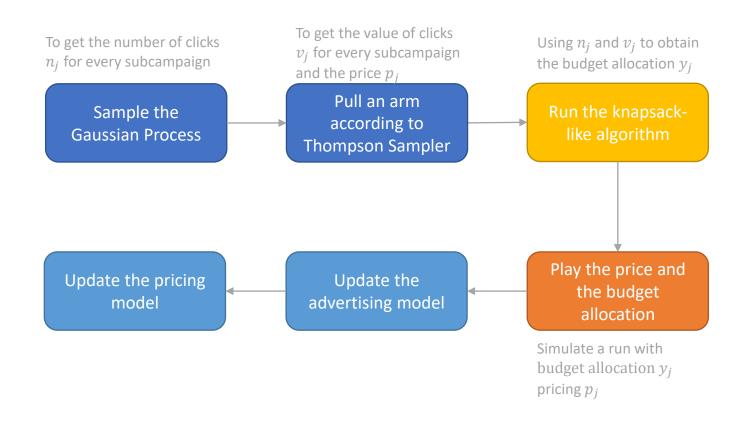

The problem can be formulated as:1

$$\begin{cases} \max_{y_j} \sum_{j}^{N} v_j(p_j) n_j(y_j) \\ \sum_{j}^{N} y_j < Y \end{cases}$$

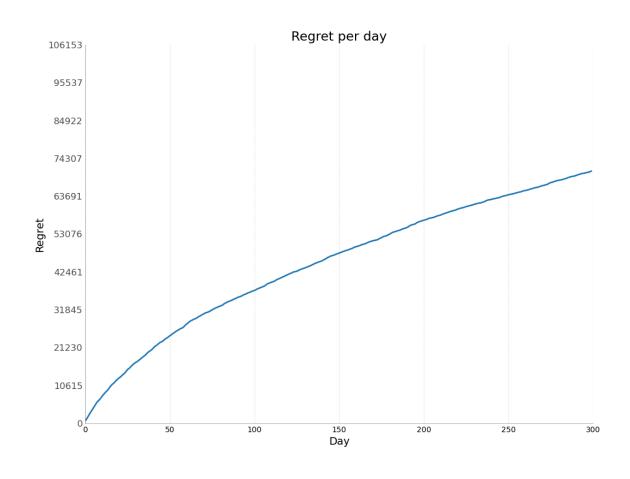

Where we add a value to the clicks.

We solve it using:

- Thompson Sampler for the pricing
- Gaussian Process Thompson Sampler for the budget allocation
- A knapsack-like algorithm to solve the system

¹: under the assumption that all and only users of context j will buy a product from advertising campaign j.

Setup

- 10 possible prices
- 11 possible budgets
- Play for 300 days
- One campaign for women under 30, one for women over 30, one for male

- Steep initial increase, slow downs after few days
- Ideal budget allocation found reliably after ~100 days
- Pricing slower convergence, hence, the continuous increase

SIMULTANUES OPTIMIZATION

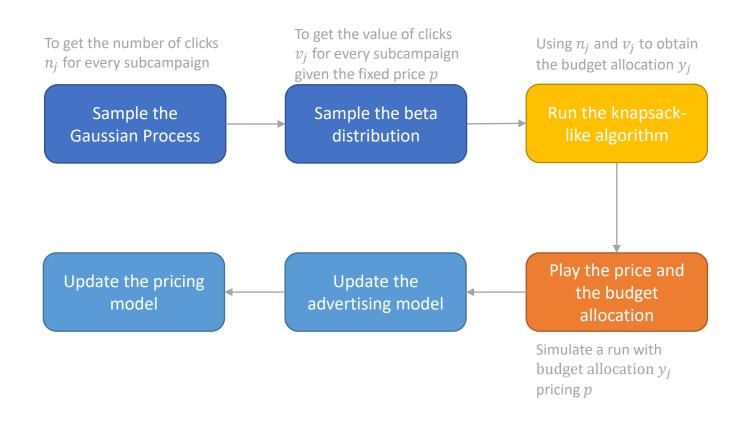

with a unique price

The problem can be formulated as:1

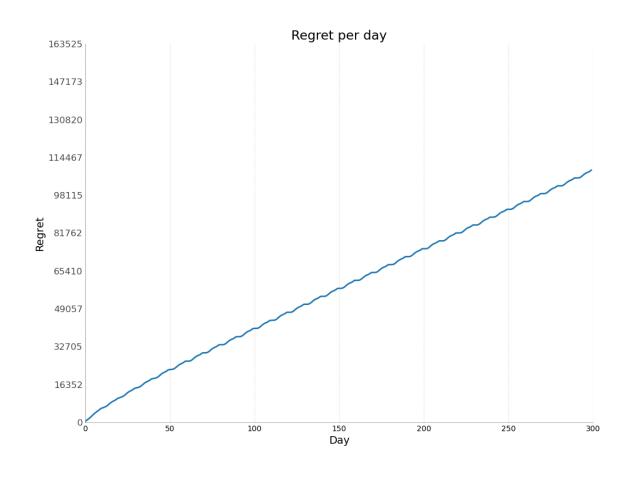

$$\begin{cases} \max_{y_j} \sum_{j}^{N} v_j(p) n_j(y_j) \\ \sum_{j}^{N} y_j < Y \end{cases}$$

It's the same problem as before, but the price is **unique** for all the contexts.

We solve this by cycling all the possible prices, playing a different and unique price every day.

¹: under the assumption that all and only users of context j will buy a product from advertising campaign j.

Setup

- 10 possible prices
- 11 possible budgets
- Play for 300 days
- One campaign for women under 30, one for women over 30, one for male
- Play a new price every 10 days

- The regret will always increase
- Convergence to the ideal budget allocation
- Saw-like behavior: regret increases when price is not ideal
- No implicit learning of the pricing
